1. The Problem Statement

THE ONE-PARAGRAPH PAPER SUMMARY

In resected non-small cell lung cancer patients, when a tumor-immune neighborhood composition score W_i is derived from 10x Visium spatial transcriptomics data and entered as a continuous covariate in a Cox proportional hazards model for overall survival, the partial likelihood estimator of the log-hazard ratio β is **biased toward the null** because W_i is a noisy estimate of a latent spatial feature X_i, and the noise variance is **heteroscedastic** — it varies across patients as a function of tissue spot count m_i and spatial autocorrelation ρ_i. We develop a **generalized regression calibration** method with patient-specific reliability ratios λ_i and demonstrate via simulation that it reduces bias by 85–95%, restores confidence interval coverage to near-nominal (93–95%), and recovers 70–80% of the power lost to measurement error.

2. The Running Example: 10 Lung Cancer Patients

We will use these 10 fictitious patients throughout the entire document. Every formula will be computed on this data so you can see exactly how the numbers work.

Our 10 Patients

Patient i	X_i (true score)	m_i (spots)	ρ_i (Moran's I)	σ_i^2 (error var)	U_i (error)	W_i (observed)	T_i (survival, months)	δ_i
1	0.72	3200	0.15	0.0147	+0.04	0.76	48	1
2	0.35	800	0.55	0.0273	−0.08	0.27	12	1
3	0.58	4500	0.10	0.0141	+0.02	0.60	36	0
4	0.41	600	0.70	0.0318	+0.12	0.53	18	1
5	0.65	2800	0.20	0.0158	−0.03	0.62	42	1
6	0.28	1500	0.40	0.0213	+0.06	0.34	8	1
7	0.50	3800	0.12	0.0143	−0.01	0.49	30	0
8	0.82	5000	0.08	0.0134	+0.01	0.83	60	1
9	0.20	400	0.80	0.0365	−0.15	0.05	6	1
10	0.55	2000	0.30	0.0185	+0.05	0.60	24	1

What each column means:

- X_i: The **true** tumor-immune neighborhood score (unknown in real life — we know it here because this is a simulation/example)
- m_i: Number of tissue spots measured for this patient (more spots = more precise)
- ρ_i: Moran's I of the spatial expression pattern in this patient's tissue (higher = more autocorrelated = noisier score)
- σ_i^2: The error variance for this patient (computed from m_i and ρ_i)
- U_i: The actual measurement error (unknown in real life)
- $W_i = X_i + U_i$: What we actually observe
- T_i: Survival time in months
- δ_i: 1 = died, 0 = censored (still alive at last contact)

Key observation: Patient 9 has only 400 spots and high autocorrelation ($\rho_9 = 0.80$), giving the **largest error variance** ($\sigma_9^2 = 0.0365$) and the biggest error ($U_9 = -0.15$). Their observed score $W_9 = 0.05$ is far from their true score $X_9 = 0.20$. Patient 8 has 5000 spots and low autocorrelation, so their measurement is very precise ($U_8 = +0.01$).

3. The True Cox Model (What We Want)

If we could observe the true spatial feature X_i for each patient, we would fit:

THE IDEAL COX MODEL

$$h(t \mid X_i) = h_0(t) \cdot \exp(\beta \cdot X_i)$$

where:

- $h(t \mid X_i)$ = hazard of death at time t for patient i
- $h_0(t)$ = baseline hazard (unspecified)
- β = log-hazard ratio per 1-unit increase in the true spatial score
- $\text{HR} = e^{\beta}$ = hazard ratio

Example: True $\beta = -1.5$ (HR = $e^{-1.5}$ = 0.223)

This means: a patient with a 1-unit higher true immune neighborhood score has only 22.3% of the death hazard — a **strongly protective** biomarker. Each 0.1-unit increase in X_i multiplies the hazard by $e^{-1.5 \times 0.1} = e^{-0.15} = 0.861$ (13.9% lower hazard).

For Patient 1 ($X_1 = 0.72$) vs Patient 9 ($X_9 = 0.20$):

$$\frac{h(t \mid X_1)}{h(t \mid X_9)} = \frac{e^{-1.5 \times 0.72}}{e^{-1.5 \times 0.20}} = e^{-1.5 \times (0.72 - 0.20)} = e^{-0.78} = 0.458$$

Patient 1 has less than half the death risk of Patient 9 at any time point. The immune score is highly protective.

3.1 The Partial Likelihood

HOW COX ESTIMATES β — STEP BY STEP

Order the death times: $t_9 = 6,\ t_6 = 8,\ t_2 = 12,\ t_4 = 18,\ t_{10} = 24,\ t_5 = 42,\ t_1 = 48,\ t_8 = 60.$

(Patients 3 and 7 are censored — they don't contribute death times but stay in risk sets.)

At $t_9 = 6$ (Patient 9 dies), risk set $R_1 = \{1, 2, 3, 4, 5, 6, 7, 8, 9, 10\}$ (all 10 alive):

$$L_1(\beta) = \frac{e^{\beta X_9}}{\sum_{k \in R_1} e^{\beta X_k}} = \frac{e^{-1.5 \times 0.20}}{e^{-1.5 \times 0.72} + e^{-1.5 \times 0.35} + \cdots + e^{-1.5 \times 0.55}}$$

Numerator: $e^{-0.30} = 0.741$

Denominator (all 10 patients):

```
Patient:   1      2      3      4      5      6      7      8      9      10
X_i:     0.72   0.35   0.58   0.41   0.65   0.28   0.50   0.82   0.20   0.55
βX_i:   -1.08  -0.525 -0.87  -0.615 -0.975 -0.42  -0.75  -1.23  -0.30  -0.825
exp():   0.340  0.591  0.419  0.541  0.377  0.657  0.472  0.292  0.741  0.438
Sum = 4.868
```

$$L_1(\beta = -1.5) = \frac{0.741}{4.868} = 0.152$$

The full partial likelihood multiplies these terms for all 8 death times. Maximizing $\log L(\beta)$ over β gives $\hat{\beta}_{\text{true}}$.

Key point: Patient 9 (who died first) has the lowest X_i (worst immune score) — so the model correctly assigns them the highest hazard. That's why $e^{\beta X_9}$ appears in the numerator with a relatively large value.

4. The Measurement Error Model

In reality, we **never observe** X_i. We observe W_i, a noisy version.

THE STRUCTURAL MEASUREMENT ERROR MODEL

$$\begin{aligned} X_i &\sim N(\mu_X, \sigma_X^2) && \text{(latent biomarker)} \\ U_i \mid X_i, m_i, \rho_i &\sim N(0, \sigma_i^2) && \text{(measurement error)} \\ W_i &= X_i + U_i && \text{(observed score)} \\ \sigma_i^2 &= \alpha_0 + \frac{\alpha_1}{m_i} + \alpha_2 \rho_i && \text{(heteroscedastic variance)} \end{aligned}$$

4.1 What Each Assumption Means (In Plain English)

Think of it this way: Each patient's tumor is like a landscape. X_i is the "true elevation" of a specific point. To measure it, you drop measuring sticks at m_i locations and average them. If the terrain is smooth (low ρ_i), the average is accurate. If the terrain is rugged (high ρ_i), nearby sticks give similar readings (autocorrelated), so you have fewer "independent" measurements than you think, and your average is noisier.

Assumption	Formula	Plain English
Structural model	$X_i \sim N(\mu_X, \sigma_X^2)$	The true biomarker values across patients come from a bell curve. Some patients have naturally higher immune neighborhoods than others.
Mean-zero error	$\mathbb{E}[U_i] = 0$	The measurement doesn't systematically over- or under-estimate. It scatters randomly around the truth.
Non-differential	$U_i \perp T_i \mid X_i$	The measurement error doesn't predict survival. If I tell you the true score, knowing the error gives no extra survival information.
Heteroscedastic	$\sigma_i^2 = \alpha_0 + \alpha_1/m_i + \alpha_2\rho_i$	Different patients have different noise levels. More spots → less noise. More autocorrelation → more noise.

4.2 Computing σ_i^2 for Our Patients

Example with $\alpha_0 = 0.01$, $\alpha_1 = 5$, $\alpha_2 = 0.03$

For Patient 2 ($m_2 = 800$ spots, $\rho_2 = 0.55$):

$$\sigma_2^2 = 0.01 + \frac{5}{800} + 0.03 \times 0.55 = 0.01 + 0.00625 + 0.0165 = \mathbf{0.0328}$$

For Patient 8 ($m_8 = 5000$ spots, $\rho_8 = 0.08$):

$$\sigma_8^2 = 0.01 + \frac{5}{5000} + 0.03 \times 0.08 = 0.01 + 0.001 + 0.0024 = \mathbf{0.0134}$$

Patient 2's error is **2.4 times larger** than Patient 8's. This is heteroscedasticity — different patients, different noise levels.

Patient	m_i	ρ_i	σ_i^2	σ_i (std dev)	Measurement quality
9	400	0.80	0.0365	0.191	Worst
4	600	0.70	0.0318	0.178	Poor
2	800	0.55	0.0273	0.165	Below average
6	1500	0.40	0.0213	0.146	Average
10	2000	0.30	0.0185	0.136	Above average
5	2800	0.20	0.0158	0.126	Good
1	3200	0.15	0.0147	0.121	Good
7	3800	0.12	0.0143	0.120	Good
3	4500	0.10	0.0141	0.119	Very good
8	5000	0.08	0.0134	0.116	Best

5. Attenuation Bias: Why the Naive Estimator Is Wrong

5.1 The Naive Model (What Everyone Does)

Since we don't know X_i, we plug W_i directly into Cox:

$$h(t \mid W_i) = h_0(t) \cdot \exp(\tilde{\beta} \cdot W_i)$$

The naive estimate $\tilde{\beta}$ is **not** equal to the true β.

5.2 The Attenuation Result

DERIVATION OF ATTENUATION BIAS

Under the structural model with homoscedastic error (constant σ_U^2), the naive estimator converges to:

$$\tilde{\beta} \xrightarrow{p} \beta \cdot \lambda$$

where the **reliability ratio** is:

$$\lambda = \frac{\sigma_X^2}{\sigma_X^2 + \sigma_U^2} = \frac{\text{Var(signal)}}{\text{Var(signal)} + \text{Var(noise)}}$$

Why? The key insight comes from the linear regression case. With the true model $Y = \beta X + \epsilon$ and observed $W = X + U$:

$$\begin{aligned}
\tilde{\beta} &= \frac{\text{Cov}(W, Y)}{\text{Var}(W)} && (1)\\
&= \frac{\text{Cov}(X + U, \beta X + \epsilon)}{\text{Var}(X + U)} && (2)\\
&= \frac{\beta \cdot \text{Var}(X) + 0 + 0 + 0}{\text{Var}(X) + \text{Var}(U)} \quad \text{(by independence)} && (3)\\
&= \beta \cdot \frac{\text{Var}(X)}{\text{Var}(X) + \text{Var}(U)} && (4)\\
&= \beta \cdot \lambda && (5)
\end{aligned}$$

Since $\lambda < 1$ always (you always add positive noise), $|\tilde{\beta}| < |\beta|$. The estimate is **shrunk toward zero**. This is called **attenuation bias**.

The same result holds approximately for the Cox partial likelihood estimator (Prentice, 1982).

5.3 Computing the Attenuation on Our Example

Numerical Computation

From our 10 patients:

$$\mu_X = \frac{0.72 + 0.35 + \cdots + 0.55}{10} = 0.506$$

$$\sigma_X^2 = \mathrm{Var}(X_i) = \frac{1}{10}\sum (X_i - 0.506)^2 = 0.0344$$

$$\bar{\sigma}_U^2 = \frac{1}{10}\sum \sigma_i^2 = \frac{0.0147 + 0.0273 + \cdots + 0.0185}{10} = 0.0208$$

Homoscedastic reliability ratio (using average error variance):

$$\lambda = \frac{0.0344}{0.0344 + 0.0208} = \frac{0.0344}{0.0552} = \mathbf{0.623}$$

With true $\beta = -1.5$:

$$\tilde{\beta} \approx -1.5 \times 0.623 = \mathbf{-0.935}$$

$$\mathrm{HR}_{\text{naive}} = e^{-0.935} = 0.393 \quad \text{vs} \quad \mathrm{HR}_{\text{true}} = e^{-1.5} = 0.223$$

The naive analysis says HR = 0.39 (moderate effect). The truth is HR = 0.22 (strong effect). You've lost 38% of the signal!

A reviewer reading your paper would conclude: "the spatial biomarker shows a moderate protective association." The correct conclusion is: "the spatial biomarker shows a *strong* protective association, attenuated by measurement error."

6. The Reliability Ratio λ

FORMAL DEFINITION

$$\lambda = \frac{\sigma_X^2}{\sigma_X^2 + \sigma_U^2} = \frac{\text{signal variance}}{\text{total variance of observed score}}$$

Analogy — Radio Signal: λ is like the signal-to-total-power ratio in a radio. If the signal is strong relative to static (λ near 1), you hear the music clearly. If the static dominates (λ near 0), you can barely hear the music. Regression calibration is like noise-canceling headphones — it amplifies the signal based on how much static there is.

λ	σ_U^2 relative to σ_X^2	Attenuation	Situation
0.95	Very small	5%	Excellent measurement, large panels
0.80	Small	20%	Good measurement

0.60	Comparable	40%	Typical spatial omics scenario
0.40	Large	60%	Small panel, high autocorrelation
0.20	Dominant	80%	Almost all noise — score is useless

7. Why One λ Is Not Enough: Heteroscedasticity

The Central Innovation of Your Paper

Standard regression calibration uses **one** λ for all patients. But in spatial omics, different patients have different noise levels. A single λ over-corrects precise patients and under-corrects noisy patients.

Example: Why One λ Fails

Using $\lambda = 0.623$ for everyone:

Patient	σ_i^2	True λ_i	Global λ	Error in correction
8 (5000 spots, low ρ)	0.0134	$\frac{0.0344}{0.0344+0.0134} = 0.720$	0.623	Over-shrinks by 13%
9 (400 spots, high ρ)	0.0365	$\frac{0.0344}{0.0344+0.0365} = 0.485$	0.623	Under-shrinks by 28%

Patient 8 has a precise measurement — it should barely be shrunk ($\lambda_8 = 0.72$). But the global $\lambda = 0.62$ shrinks it too much.

Patient 9 has a noisy measurement — it should be shrunk heavily ($\lambda_9 = 0.49$). But $\lambda = 0.62$ doesn't shrink it enough.

The global correction treats a 5000-spot patient the same as a 400-spot patient. That is statistically wrong.

8. Patient-Specific λ_i (Your Contribution)

THE GENERALIZED RELIABILITY RATIO

$$\boxed{\lambda_i = \frac{\sigma_X^2}{\sigma_X^2 + \sigma_i^2}}$$

Each patient gets their own shrinkage factor based on their measurement quality.

Computing λ_i for All 10 Patients

Using $\sigma_X^2 = 0.0344$:

Patient	σ_i^2	$\sigma_X^2 + \sigma_i^2$	λ_i	Interpretation
8	0.0134	0.0478	**0.720**	Trust the observed score (shrink 28%)
3	0.0141	0.0485	0.709	Trust the score
7	0.0143	0.0487	0.706	Trust the score
1	0.0147	0.0491	0.701	Trust the score
5	0.0158	0.0502	0.686	Moderate trust
10	0.0185	0.0529	0.651	Moderate trust
6	0.0213	0.0557	0.618	Less trust
2	0.0273	0.0617	0.558	Shrink toward mean
4	0.0318	0.0662	0.520	Shrink more
9	0.0365	0.0709	**0.485**	Shrink heavily (trust mean more)

λ_i ranges from 0.485 (Patient 9, noisiest) to 0.720 (Patient 8, most precise). The 48% spread in λ_i shows why a single global λ is inadequate.

9. Estimating the Error Variance σ_i^2

In real data, we don't know σ_i^2. We must estimate it. This is the **identification problem**.

9.1 The Spot-Level Bootstrap

ALGORITHM: PARAMETRIC BOOTSTRAP FOR Σ_I^2

For each patient i:

1. You have m_i spots with cell-type annotations and spatial coordinates
2. For $b = 1, \ldots, B$ (e.g., $B = 200$):
   - Randomly subsample $\lfloor 0.8 \times m_i \rfloor$ spots (80% of spots)
   - Reconstruct the spatial graph on the subsampled spots
   - Recompute the neighborhood composition score $W_i^{(b)}$
3. Estimate: $\hat{\sigma}_i^2 = \mathrm{Var}(W_i^{(1)}, \ldots, W_i^{(B)}) \times \text{correction factor}$

The correction factor accounts for the fact that subsampling 80% underestimates the variance of the full-sample estimator. Under simple random sampling: correction $\approx 0.80/(1 - 0.80) = 4.0$.

9.2 The Parametric Variance Model

FITTING THE VARIANCE MODEL

Once you have $\hat{\sigma}_i^2$ for each patient from the bootstrap, fit:

$$\hat{\sigma}_i^2 = \alpha_0 + \frac{\alpha_1}{m_i} + \alpha_2 \rho_i + \epsilon_i$$

using ordinary least squares or weighted least squares. This gives you $\hat{\alpha}_0, \hat{\alpha}_1, \hat{\alpha}_2$.

Then, the **smoothed** variance estimate:

$$\tilde{\sigma}_i^2 = \hat{\alpha}_0 + \frac{\hat{\alpha}_1}{m_i} + \hat{\alpha}_2 \rho_i$$

Smoothing through the parametric model is better than using raw bootstrap estimates because it borrows strength across patients and avoids overfitting to individual bootstrap noise.

10. Estimating the Signal Variance σ_X^2

METHOD OF MOMENTS IDENTIFICATION

The variance of the observed scores decomposes as:

$$\mathrm{Var}(W_i) = \mathrm{Var}(X_i + U_i) = \mathrm{Var}(X_i) + \mathrm{Var}(U_i) = \sigma_X^2 + \mathbb{E}[\sigma_i^2]$$

(The cross-term $2\mathrm{Cov}(X_i, U_i) = 0$ by the non-differential assumption.)

Therefore:

$$\boxed{\hat{\sigma}_X^2 = \max\left\{\widehat{\mathrm{Var}}(W_i) - \frac{1}{n}\sum_{i=1}^{n}\hat{\sigma}_i^2,\ \ 0\right\}}$$

Numerical Computation

$$\widehat{\mathrm{Var}}(W_i) = \mathrm{Var}(0.76, 0.27, 0.60, 0.53, 0.62, 0.34, 0.49, 0.83, 0.05, 0.60)$$

$$\bar{W} = 0.509$$

$$\widehat{\mathrm{Var}}(W_i) = \frac{1}{10}\sum(W_i - 0.509)^2 = 0.0486$$

$$\frac{1}{n}\sum\hat{\sigma}_i^2 = 0.0208$$

$$\hat{\sigma}_X^2 = \max\{0.0486 - 0.0208,\ 0\} = \max\{0.0278,\ 0\} = \mathbf{0.0278}$$

(Note: the true $\sigma_X^2 = 0.0344$. Our estimate is a bit low because $n = 10$ is tiny. With $n = 100$ patients, the estimate would be much closer.)

11. The Regression Calibration Correction

THE CORE FORMULA

Replace W_i with the **best prediction of** X_i **given** W_i:

$$\boxed{\hat{X}_i = \hat{\mu}_X + \hat{\lambda}_i(W_i - \hat{\mu}_W)}$$

where:

$$\hat{\mu}_W = \bar{W} = \frac{1}{n}\sum W_i, \qquad \hat{\mu}_X \approx \hat{\mu}_W \quad (\text{since } \mathbb{E}[U_i] = 0)$$

$$\hat{\lambda}_i = \frac{\hat{\sigma}_X^2}{\hat{\sigma}_X^2 + \hat{\sigma}_i^2}$$

What this formula does intuitively:

- Start at the population mean $\hat{\mu}_W$
- Move toward the observed value W_i by a fraction $\hat{\lambda}_i$
- If measurement is precise ($\hat{\lambda}_i$ near 1): $\hat{X}_i \approx W_i$ — trust the observation
- If measurement is noisy ($\hat{\lambda}_i$ near 0): $\hat{X}_i \approx \hat{\mu}_W$ — trust the population mean

Computing $\hat{X}_i$ for All 10 Patients

Using $\hat{\mu}_W = 0.509$ and $\hat{\sigma}_X^2 = 0.0278$:

Patient	W_i	$\hat{\sigma}_i^2$	$\hat{\lambda}_i$	$W_i - \hat{\mu}_W$	$\hat{X}_i$	True X_i	Error
1	0.76	0.0147	0.654	+0.251	0.673	0.72	−0.047
2	0.27	0.0273	0.504	−0.239	0.389	0.35	+0.039
3	0.60	0.0141	0.663	+0.091	0.569	0.58	−0.011
4	0.53	0.0318	0.466	+0.021	0.519	0.41	+0.109
5	0.62	0.0158	0.638	+0.111	0.580	0.65	−0.070
6	0.34	0.0213	0.566	−0.169	0.413	0.28	+0.133
7	0.49	0.0143	0.660	−0.019	0.496	0.50	−0.004
8	0.83	0.0134	0.675	+0.321	0.726	0.82	−0.094
9	0.05	0.0365	0.432	−0.459	0.311	0.20	+0.111
10	0.60	0.0185	0.600	+0.091	0.564	0.55	+0.014

Key observations:

- **Patient 9:** Observed $W_9 = 0.05$ (far from truth 0.20). Calibrated $\hat{X}_9 = 0.311$ — pulled strongly toward the mean because $\lambda_9 = 0.432$. Still not perfect, but much closer to the truth than 0.05.
- **Patient 7:** Observed $W_7 = 0.49$, calibrated $\hat{X}_7 = 0.496$ — barely changed because the measurement was already close to truth ($X_7 = 0.50$) and $\lambda_7 = 0.66$ is moderately high.
- **Average error:** $|W_i - X_i|$ average = 0.057. $|\hat{X}_i - X_i|$ average = 0.063. Wait — the calibrated values aren't always closer to the truth for individual patients! But on average, the **regression coefficient** $\hat{\beta}$ will be closer to β. That's the key — RC corrects the regression, not individual scores.

12. The Corrected Cox Model

THE CORRECTED ESTIMATOR

Replace W_i with $\hat{X}_i$ in the Cox partial likelihood:

$$h(t \mid \hat{X}_i) = h_0(t) \cdot \exp(\hat{\beta}_{\mathrm{RC}} \cdot \hat{X}_i)$$

Maximize the partial likelihood with $\hat{X}_i$ instead of W_i to get $\hat{\beta}_{\mathrm{RC}}$.

Under correct specification, $\hat{\beta}_{\mathrm{RC}}$ is approximately consistent for β.

What Changes in Practice

Estimator	$\hat{\beta}$	$\widehat{\mathrm{HR}}$	Bias
True (oracle)	−1.500	0.223	0
Naive (uses W_i)	−0.935	0.393	+0.565 (38% attenuation)
Corrected (uses $\hat{X}_i$)	−1.380	0.252	+0.120 (8% residual)

The correction recovers most of the lost signal: from 38% attenuation down to 8%.

13. SIMEX as Sensitivity Analysis

SIMEX ALGORITHM

1. For each noise multiplier $\zeta \in \{0.5, 1.0, 1.5, 2.0\}$:
   - Generate: $W_i^{(\zeta)} = W_i + \sqrt{\zeta} \cdot Z_i$, where $Z_i \sim N(0, \hat{\sigma}_i^2)$
   - Fit Cox on $\{W_i^{(\zeta)}\}$, get $\hat{\beta}(\zeta)$
   - Repeat B times and average to get $\bar{\hat{\beta}}(\zeta)$
2. Also compute $\bar{\hat{\beta}}(0) = \hat{\beta}_{\mathrm{naive}}$ (original data, $\zeta = 0$)
3. Fit a curve through $(\zeta, \bar{\hat{\beta}}(\zeta))$ for $\zeta \in \{0, 0.5, 1, 1.5, 2\}$
4. Extrapolate to $\zeta = -1$: $\hat{\beta}_{\mathrm{SIMEX}} = \bar{\hat{\beta}}(-1)$

Numerical Example

ζ	**Added noise**	$\bar{\hat{\beta}}(\zeta)$
−1 (extrapolated)	None (hypothetical)	**−1.42** (SIMEX estimate)
0	Original data	−0.935
0.5	$\sqrt{0.5} \times \hat{\sigma}_i$	−0.78
1.0	$1 \times \hat{\sigma}_i$	−0.65
1.5	$\sqrt{1.5} \times \hat{\sigma}_i$	−0.55
2.0	$\sqrt{2} \times \hat{\sigma}_i$	−0.47

The pattern: as you add more noise (ζ increases), $\hat{\beta}$ shrinks toward zero. Fitting a quadratic curve through these points and extrapolating to $\zeta = -1$ gives $\hat{\beta}_{\text{SIMEX}} = -1.42$, close to the true -1.50.

SIMEX doesn't require specifying the calibration model. It's model-free in that sense. Use it to **confirm** your RC results — if RC gives -1.38 and SIMEX gives -1.42, you have consistent evidence.

14. Variance of the Corrected Estimator

SANDWICH VARIANCE ESTIMATOR

The variance of $\hat{\beta}_{\text{RC}}$ must account for two sources of uncertainty:

1. Sampling variability of the Cox partial likelihood
2. Estimation uncertainty in $\hat{X}_i$ (because $\hat{\lambda}_i$ and $\hat{\sigma}_X^2$ are themselves estimated)

$$\widehat{\text{Var}}(\hat{\beta}_{\text{RC}}) = \underbrace{I^{-1}(\hat{\beta}_{\text{RC}})}_{\text{Cox information}} + \underbrace{\mathbf{D}^\top \boldsymbol{\Sigma}_\alpha \mathbf{D}}_{\text{propagated from } \hat{\alpha} \text{ estimation}}$$

where $I(\hat{\beta})$ is the observed Fisher information from the Cox partial likelihood, $\mathbf{D} = \partial\hat{\beta}/\partial\hat{\boldsymbol{\alpha}}$ is the sensitivity of $\hat{\beta}$ to the variance model parameters, and $\boldsymbol{\Sigma}_\alpha$ is the covariance matrix of $\hat{\boldsymbol{\alpha}} = (\hat{\alpha}_0, \hat{\alpha}_1, \hat{\alpha}_2)$.

In practice, use a **nonparametric bootstrap**: resample patients with replacement, re-estimate everything ($\hat{\sigma}_i^2$, $\hat{\sigma}_X^2$, $\hat{\lambda}_i$, $\hat{X}_i$, $\hat{\beta}_{\text{RC}}$), and take the bootstrap variance.

15. The Simulation Study Design

COMPLETE DATA-GENERATING MECHANISM

Step 1: Generate patient-level truth

$$X_i \sim N(\mu_X = 0.5,\ \sigma_X^2), \quad i = 1, \ldots, n$$

Vary $\sigma_X^2 \in \{0.02, 0.04, 0.08\}$.

Step 2: Generate tissue characteristics

$$m_i \sim \text{Uniform}(200, 5000), \quad \rho_i \sim \text{Beta}(2, 5)$$

Step 3: Generate error

$$\sigma_i^2 = \alpha_0 + \alpha_1/m_i + \alpha_2\rho_i, \quad U_i \sim N(0, \sigma_i^2)$$
$$W_i = X_i + U_i$$

Step 4: Generate survival

$$T_i \sim \text{Weibull}(k = 1.5,\ \lambda_i), \quad \lambda_i = \exp(-\beta X_i)/\gamma$$

where γ controls the time scale. Vary $\beta \in \{0, -0.5, -1.0, -1.5, -2.0\}$.

Step 5: Generate censoring

$$C_i \sim \text{Uniform}(0, \tau)$$

Choose τ to give censoring rates $\in \{10\%, 30\%, 50\%\}$.

Step 6: Observe

$$(\tilde{T}_i, \delta_i) = (\min(T_i, C_i),\ \mathbb{1}[T_i \leq C_i])$$

Simulation Scenarios

Parameter	Values	Purpose
n (patients)	20, 50, 100, 200	Realistic sample sizes for spatial omics
β (true effect)	0, −0.5, −1.0, −1.5, −2.0	$\beta = 0$ for Type I error; others for power
σ_X^2	0.02, 0.04, 0.08	Low/medium/high between-patient variability

$\alpha_0, \alpha_1, \alpha_2$	Fixed: 0.01, 5, 0.03	Error variance model (from calibration data)
Censoring rate	10%, 30%, 50%	Impact of information loss
Variance model misspecification	Correct vs. omit ρ_i term	Robustness to model misspecification

Total: $4 \times 5 \times 3 \times 3 \times 2 = 360$ scenarios, each with $R = 2000$ replications = 720,000 simulated datasets.

16. Performance Metrics

WHAT WE MEASURE IN EACH SCENARIO

Metric	Formula	Target
Bias	$\frac{1}{R}\sum_{r=1}^{R}\hat{\beta}^{(r)} - \beta$	Near 0
Relative bias	$\lvert\text{Bias}\rvert/\lvert\beta\rvert$ (when $\beta \neq 0$)	$< 5\%$
Empirical SE	$\text{Std}(\hat{\beta}^{(1)}, \ldots, \hat{\beta}^{(R)})$	—
Average model SE	$\frac{1}{R}\sum \widehat{\text{SE}}^{(r)}$	Close to empirical SE
MSE	$\text{Bias}^2 + \text{Var}$	Minimal
Coverage	$\frac{1}{R}\sum \mathbb{1}[\beta \in \text{CI}^{(r)}]$	93–97% for nominal 95%
Type I error	Rejection rate when $\beta = 0$	4–6% for nominal 5%
Power	Rejection rate when $\beta \neq 0$	As high as possible

Example Results Table (What Your Paper Will Show)

$n = 50$, $\beta = -1.5$, 30% censoring, $\sigma_X^2 = 0.04$:

Method	$\overline{\hat{\beta}}$	Bias	Rel. Bias	SE	MSE	Coverage	Power
Oracle (X_i known)	−1.51	−0.01	0.7%	0.38	0.144	95.2%	82%
Naive (uses W_i)	**−0.93**	**+0.57**	**38%**	0.29	**0.409**	**42%**	58%
RC-global (one λ)	−1.32	+0.18	12%	0.41	0.200	84%	71%
RC-patient (λ_i)	**−1.45**	**+0.05**	**3.3%**	0.43	**0.187**	**93.8%**	76%
SIMEX	−1.41	+0.09	6%	0.44	0.202	91.5%	73%

Reading this table (the payoff of the entire paper):

- **Naive:** 38% bias, 42% coverage (catastrophic — only 42% of CIs contain the truth instead of 95%), power = 58%
- **RC-global (standard textbook approach):** Better than naive but still 12% bias and 84% coverage. The single-λ correction is **insufficient**.
- **RC-patient (your method):** 3.3% bias, 93.8% coverage (near nominal), power = 76%. **This is the contribution.**
- **SIMEX:** 6% bias, 91.5% coverage. Decent, confirms RC direction, slightly worse because extrapolation is approximate.
- **Oracle:** The best achievable. Your RC-patient method gets within 6% of the oracle on every metric.

17. Complete Paper Outline

Paper Structure for Biostatistics Submission

1. Introduction (2 pages)

- Spatial transcriptomics in cancer: biomarker potential
- The measurement error problem: nobody corrects for it
- The heteroscedastic structure: why standard RC fails
- Our contribution in one sentence

2. Model and Methods (5 pages)

- 2.1 The Cox model with true covariate X_i
- 2.2 The structural measurement error model ($W_i = X_i + U_i$)
- 2.3 The heteroscedastic variance model ($\sigma_i^2 = \alpha_0 + \alpha_1/m_i + \alpha_2\rho_i$)
- 2.4 Patient-specific reliability ratios λ_i
- 2.5 Generalized regression calibration estimator
- 2.6 Estimation of variance components (bootstrap + method of moments)
- 2.7 Variance estimation for $\hat{\beta}_{\mathrm{RC}}$
- 2.8 SIMEX as sensitivity analysis

3. Simulation Study (4 pages)

- 3.1 Data-generating mechanism (Section 15 of this document)
- 3.2 Scenarios and parameters
- 3.3 Performance metrics
- 3.4 Results: bias, coverage, MSE, power comparisons
- 3.5 Sensitivity to variance model misspecification

4. Application to NSCLC Spatial Data (3 pages)

- 4.1 Dataset description
- 4.2 Computing W_i and estimating $\hat{\sigma}_i^2$
- 4.3 Naive vs corrected Cox results
- 4.4 SIMEX confirmation

5. Discussion (2 pages)

- 5.1 Summary of findings
- 5.2 Limitations: X_i is never observed; graph-conditionality; normality assumption
- 5.3 Extensions: Beta structural model; time-varying spatial features
- 5.4 Implications for spatial biomarker research

Supplementary Material

- Proofs of consistency
- Additional simulation scenarios
- Software code (R package)

THE COMPLETE MATHEMATICAL CHAIN IN ONE BOX

1. True model:	$h(t\|X_i) = h_0(t)e^{\beta X_i}$
2. Latent:	$X_i \sim N(\mu_X, \sigma_X^2)$
3. Error:	$W_i = X_i + U_i, \quad U_i \sim N(0, \sigma_i^2)$
4. Heteroscedasticity:	$\sigma_i^2 = \alpha_0 + \alpha_1/m_i + \alpha_2\rho_i$
5. Attenuation:	$\tilde{\beta} \xrightarrow{p} \beta \cdot \lambda, \quad \lambda < 1$
6. Patient-specific λ_i:	$\lambda_i = \sigma_X^2/(\sigma_X^2 + \sigma_i^2)$
7. Calibrated covariate:	$\hat{X}_i = \hat{\mu}_W + \hat{\lambda}_i(W_i - \hat{\mu}_W)$
8. Corrected model:	$h(t\|\hat{X}_i) = h_0(t)e^{\hat{\beta}_{\mathrm{RC}}\hat{X}_i}$
9. Identification:	$\hat{\sigma}_X^2 = \max\{\widehat{\mathrm{Var}}(W) - \bar{\hat{\sigma}}_U^2,\ 0\}$
