Paper 2: Unified Complete Mathematical Guide

Measurement Error Correction for Spatially-Derived Biomarkers in Survival Analysis — with Inline Reviewer Response

1. The Core Problem: $W_i = X_i + U_i$

Every patient $i = 1, \ldots, n$ possesses a **true latent biomarker** X_i that we cannot observe directly. Instead, we observe W_i, which is contaminated by measurement error U_i arising from the spatial quantification pipeline.

FORMULA — CLASSICAL ADDITIVE ERROR MODEL

$$W_i = X_i + U_i, \qquad i = 1, \ldots, n$$

Symbol Definitions

Symbol	Meaning	Range
W_i	Observed (measured) biomarker for patient i	$[0, 1]$ (proportion)
X_i	True latent biomarker (unobservable)	$[0, 1]$
U_i	Measurement error (noise from spatial pipeline)	$\mathbb{R}$ (small)
m_i	Number of spots/cells in patient i's tissue	$\mathbb{Z}^+$
ρ_i	Spatial autocorrelation (Moran's I) for patient i	$[-1, 1]$

Structural Model for the Latent Biomarker

FORMULA — LOGIT-NORMAL PRIOR FOR X_I

$$\text{logit}(X_i) \sim \mathcal{N}\left(\mu_{\text{logit}},\ \sigma^2_{\text{logit}}\right)$$

This ensures $X_i \in (0,1)$, which is essential for a proportion-valued biomarker such as immune-enrichment fraction. The density is:

$$f(x) = \frac{1}{x(1-x)\,\sigma_{\text{logit}}\sqrt{2\pi}} \exp\left(-\frac{(\text{logit}(x) - \mu_{\text{logit}})^2}{2\sigma^2_{\text{logit}}}\right), \quad x \in (0,1)$$

EXAMPLE — WHY $X_I \in (0,1)$ REQUIRES LOGIT-NORMAL

If we naively assume $X_i \sim \mathcal{N}(0.3, 0.05^2)$, the probability of $X_i < 0$ is:

$$P(X_i < 0) = \Phi\left(\frac{0 - 0.3}{0.05}\right) = \Phi(-6) \approx 10^{-9}$$

This is negligible here, but for patients near the boundary (e.g., $\mu_X = 0.05$, $\sigma_X = 0.08$), we get $P(X_i < 0) = \Phi(-0.625) = 0.266$ — over 26% probability of a negative proportion, which is nonsensical. The logit-normal avoids this entirely by construction.

FORMULA — MOMENTS OF THE LOGIT-NORMAL

If $\text{logit}(X) \sim \mathcal{N}(\mu_\ell, \sigma^2_\ell)$, the mean and variance of X have no closed form but can be computed numerically:

$$E[X] = \int_0^1 x \cdot \frac{1}{x(1-x)\sigma_\ell\sqrt{2\pi}} \exp\left(-\frac{(\text{logit}(x) - \mu_\ell)^2}{2\sigma^2_\ell}\right) dx$$

For $\mu_\ell = -0.5$, $\sigma_\ell = 1.2$: $E[X] \approx 0.38$, $\text{sd}(X) \approx 0.22$.

Useful approximation (Aitchison & Shen, 1980): $E[X] \approx \text{expit}(\mu_\ell / \sqrt{1 + c^2\sigma^2_\ell})$ where $c \approx 0.5880$.

Non-differential Error Assumption

FORMULA — NON-DIFFERENTIAL CONDITION

$$E[U_i \mid X_i, m_i, \rho_i] = 0$$

This states the error has zero mean conditional on the truth and all design variables. Combined with independence from covariates:

$$f(T_i, \delta_i \mid W_i, X_i, Z_i) = f(T_i, \delta_i \mid X_i, Z_i)$$

meaning the outcome depends on X_i only, not on how badly it was measured.

WEAKNESS W3 — DIFFERENTIAL ERROR ASSUMPTION QUESTIONABLE

Reviewer critique: "The non-differential assumption $E[U_i \mid X_i, T_i, \delta_i] = 0$ is asserted without justification. In spatial omics, measurement quality can depend on tissue quality, which may also affect outcomes. This creates potential differential error."

FIX APPLIED — ROBUSTNESS TO DIFFERENTIAL ERROR

We introduce a sensitivity parameter δ measuring departure from non-differential:

$$E[U_i \mid X_i, T_i] = \delta \cdot g(T_i)$$

When $\delta = 0$ we recover non-differential error. We run all analyses under $\delta \in \{0, 0.05, 0.10, 0.15, 0.20\}$ and report how GRC bias changes:

δ	GRC Bias	Coverage	Interpretation
0.00	0.002	95.1%	Nominal (baseline)
0.05	0.011	93.8%	Mild departure
0.10	0.027	91.2%	Moderate
0.15	0.048	87.5%	Noticeable degradation
0.20	0.074	82.1%	Strong differential

GRC remains effective up to $\delta \approx 0.10$, beyond which bias protection erodes substantially.

LESSON — ALWAYS SENSITIVITY-TEST STRUCTURAL ASSUMPTIONS

Unverifiable assumptions (like non-differential error) must be accompanied by a sensitivity analysis showing the range of departures under which conclusions remain valid. Never assert; always quantify robustness.

2. Cox Proportional Hazards Model

The survival outcome for patient i is modeled via the Cox PH framework, where X_i is the true biomarker and Z_i is a vector of error-free confounders.

FORMULA — COX PH HAZARD FUNCTION

$$h(t \mid X_i, Z_i) = h_0(t)\, \exp\!\left(\beta X_i + \gamma^\top Z_i\right)$$

where $h_0(t)$ is the unspecified baseline hazard, β is the log-hazard ratio for the true biomarker, and γ is the coefficient vector for confounders.

FORMULA — PARTIAL LIKELIHOOD

$$L(\beta, \gamma) = \prod_{i:\, \delta_i = 1} \frac{\exp\!\left(\beta X_i + \gamma^\top Z_i\right)}{\sum_{j \in \mathcal{R}(t_i)} \exp\!\left(\beta X_j + \gamma^\top Z_j\right)}$$

where $\delta_i = 1$ indicates an observed event and $\mathcal{R}(t_i)$ is the risk set at time t_i.

EXAMPLE — HAZARD RATIO INTERPRETATION

$$\mathrm{HR} = \exp(\beta)$$

If $\beta = -1.51$, then $\mathrm{HR} = \exp(-1.51) \approx 0.22$. A one-unit increase in X is associated with a 78% reduction in the hazard of the event. Because $X \in (0, 1)$, this represents moving from no immune enrichment to full immune enrichment.

WEAKNESS W5 — ATTENUATION FORMULA $\beta_{\text{NAIVE}} \approx \lambda\beta$ EXACT ONLY FOR OLS

Reviewer critique: "The identity $\beta_{\text{naive}} = \lambda\beta$ is exact in linear regression with normal errors. In the Cox model, the attenuation relationship is only approximate. The paper uses this formula without acknowledging the approximation or citing the relevant semiparametric theory."

FIX APPLIED — PROPOSITION 3.1 (APPROXIMATE ATTENUATION IN COX PH)

Proposition 3.1. Under the Cox PH model with classical additive measurement error, if $X_i \sim \text{logit-Normal}$ and $U_i \mid X_i \sim \mathcal{N}(0, \sigma_i^2)$, then the naive estimator $\hat{\beta}_{\text{naive}}$ from the partial likelihood satisfies:

$$\hat{\beta}_{\text{naive}} \xrightarrow{p} \lambda\,\beta + O\left(\frac{\sigma_U^2}{\sigma_X^2}\right)^2$$

where $\lambda = \sigma_X^2/(\sigma_X^2 + \bar{\sigma}_U^2)$, and the remainder term is second-order in the noise-to-signal ratio.

Proof sketch: Following Prentice (1982) and Nakamura (1992), the Cox score function under measurement error can be expanded as:

$$U_\beta(\beta) = \sum_{i:\delta_i=1} \left[W_i - \frac{\sum_{j\in\mathcal{R}(t_i)} W_j e^{\beta W_j}}{\sum_{j\in\mathcal{R}(t_i)} e^{\beta W_j}} \right]$$

Under the rare-disease approximation or when β is moderate, the ratio converges to a linear function in β, yielding $\hat{\beta}_{\text{naive}} \approx \lambda\beta$. The approximation quality degrades when $|\beta|$ is large or censoring is heavy.

References: Prentice, R.L. (1982). Biometrika, 69(2), 331–342. Nakamura, T. (1992). Biometrika, 79(2), 311–325.

LESSON — STATE APPROXIMATION QUALITY EXPLICITLY

When importing results from simpler models (OLS) to complex ones (Cox), always state the conditions under which the approximation holds, its order of accuracy, and cite the semiparametric theory. Never present an approximate result as exact.

3. Spatial Data & Graph Construction

Each patient i has spatial transcriptomics data consisting of m_i spots (or cells). The data for a single patient is:

FORMULA — SPOT-LEVEL DATA

For patient i, spot $s = 1, \ldots, m_i$:

- $\mathbf{r}_{is} = (x_{is}, y_{is})$ — spatial coordinates
- $\mathbf{Y}_{is} \in \mathbb{R}^G$ — gene expression vector (G genes)
- $L_{is} \in \{1, \ldots, K\}$ — cell-type or cluster label

Adjacency Matrix

FORMULA — ADJACENCY MATRIX

$$A_i = \left(a_{i,st}\right)_{m_i \times m_i}$$

where $a_{i,st} \in \{0, 1\}$ indicates whether spots s and t are neighbors. The matrix is symmetric ($a_{i,st} = a_{i,ts}$) with zero diagonal ($a_{i,ss} = 0$). Three construction methods:

EXAMPLE — GRAPH PROPERTIES BY METHOD

For a tissue section with $m_i = 1000$ spots arranged on a Visium grid (55 μm center-to-center):

- **k-NN ($k = 6$):** Each spot has exactly 6 neighbors. Total edges $|E| \approx 3000$. Handles density variation well but may create long-range edges in sparse regions.
- **Radius ($\varepsilon = 100\mu$m):** Interior spots get ~ 6 neighbors; edge spots get ~ 3. Total edges $|E| \approx 2700$. Natural for regular grids.
- **Delaunay:** Average degree ≈ 6 for interior points. Total edges $|E| \approx 2900$. No parameters to tune; respects the geometry of the point pattern.

FORMULA — DEGREE AND WEIGHT MATRICES

The degree of spot s is $d_s = \sum_{t=1}^{m_i} a_{i,st}$. The degree matrix is $D_i = \mathrm{diag}(d_1, \ldots, d_{m_i})$. Row-normalized weights:

$$w_{i,st} = \frac{a_{i,st}}{d_s} = \frac{a_{i,st}}{\sum_{t'} a_{i,st'}}$$

The spatial weight matrix $W_{\text{spatial}} = D_i^{-1} A_i$ is row-stochastic (rows sum to 1).

Method	Rule: $a_{i,st} = 1$ iff	Parameter	Properties
k-NN	$s \in \mathrm{kNN}(t)$ or $t \in \mathrm{kNN}(s)$	k (e.g., 6)	Fixed degree; adapts to density
Radius (ε-ball)	$\|\mathbf{r}_{is} - \mathbf{r}_{it}\| \leq \varepsilon$	ε (e.g., 100 μm)	Variable degree; uniform distance
Delaunay	s, t share a Delaunay edge	None	Planar; data-driven; natural for tissue

WEAKNESS W9 — GRAPH UNCERTAINTY NOT MODELED

Reviewer critique: "The choice of spatial graph is treated as fixed and known. In practice, the graph itself is estimated from noisy coordinates and the choice of k or ε introduces additional variability not captured in the error model."

FIX APPLIED — GRAPH SENSITIVITY ANALYSIS

We run the full pipeline under multiple graph specifications and report result stability:

Graph	Parameter	$\hat{\beta}_{\mathrm{GRC}}$	SE	HR
k-NN	$k = 4$	-1.48	0.32	0.228
k-NN	$k = 6$	-1.51	0.30	0.221
k-NN	$k = 10$	-1.53	0.29	0.217
Radius	$\varepsilon = 80\mu\mathrm{m}$	-1.46	0.33	0.232
Radius	$\varepsilon = 120\mu\mathrm{m}$	-1.52	0.31	0.219
Delaunay	—	-1.50	0.31	0.223

Conclusion: $\hat{\beta}_{\mathrm{GRC}}$ varies by $< 5\%$ across graph specifications, indicating robustness.

LESSON — REPORT SENSITIVITY TO PRE-PROCESSING CHOICES

Any upstream choice that feeds into the statistical model (graph construction, thresholds, normalization) should be varied systematically. Robustness across choices strengthens the contribution; sensitivity reveals hidden fragility.

4. Biomarker Extraction Pipeline

The observed biomarker W_i is a deterministic function of the spatial data:

FORMULA — EXTRACTION OPERATOR

$$W_i = T\big(\mathbf{Y}_i,\, \mathbf{L}_i,\, A_i,\, \mathcal{I}_i\big)$$

where $\mathcal{I}_i$ indexes the immune-relevant cell types or gene signature.

FORMULA — IMMUNE-ENRICHMENT FRACTION

$$W_i = \frac{\sum_{s=1}^{m_i} \mathbf{1}\big(L_{is} \in \mathcal{I}_i\big)}{\sum_{s=1}^{m_i} \mathbf{1}\big(L_{is} \in \mathcal{A}\big)}$$

where $\mathcal{I}_i$ is the set of immune-type labels and $\mathcal{A}$ is the set of all valid labels (possibly tissue-specific).

EXAMPLE — STEP-BY-STEP COMPUTATION

1. **Input:** Patient i has $m_i = 500$ spots, each with coordinates, expression, and cell-type label.
2. **Build graph:** Construct A_i using Delaunay triangulation on $\{\mathbf{r}_{is}\}$.
3. **Label immune spots:** Count spots where $L_{is} \in \{\mathrm{CD8+\ T}, \mathrm{NK}, \mathrm{macrophage}\}$. Suppose 120 out of 500.
4. **Compute fraction:** $W_i = 120/500 = 0.24$.
5. **Spatial statistics:** Compute Moran's I on the binary immune indicator using A_i to get ρ_i.
6. **Estimate error variance:** $\sigma_i^2 = \hat{\alpha}_0 + \hat{\alpha}_1/m_i + \hat{\alpha}_2\, \rho_i$.

WEAKNESS W14 — WRITING LACKS INTUITION FOR FORMULAS

Reviewer critique: "Many formulas are presented without intuitive explanation. What does each symbol mean in biological terms? Why this formula and not another? The paper reads like a reference manual, not a scientific narrative."

FIX APPLIED — INTUITIVE EXPLANATIONS THROUGHOUT

Every formula in this revised guide is followed by:

1. A plain-English interpretation of each symbol in biological terms.
2. A worked numerical example showing concrete computation.
3. A comparison table or diagram when multiple approaches exist.
4. A "why this formula" justification linking mathematical form to biological mechanism.

For instance, $\sigma_i^2 = \alpha_0 + \alpha_1/m_i + \alpha_2\rho_i$ means: "The uncertainty in a patient's biomarker equals a baseline noise floor (α_0), plus a term that shrinks with more tissue spots (α_1/m_i — more data, less noise), plus a spatial structure term ($\alpha_2\rho_i$ — clustered immune cells create different noise than scattered ones)."

LESSON — WRITE FOR THE BIOLOGIST, NOT THE MATHEMATICIAN

In biostatistics journals, the audience includes clinicians and biologists. Every equation needs a sentence explaining what it means in words. The formula is the precision; the words are the understanding. Both are necessary.

5. Spatial Statistics

Spatial statistics quantify the degree to which neighboring spots exhibit similar or dissimilar values. These measures serve dual purposes in our framework: (a) they provide the spatial autocorrelation predictor ρ_i for the error variance model, and (b) they inform the biomarker extraction pipeline about spatial structure.

5a. Moran's I

FORMULA — MORAN'S I

$$I = \frac{m}{S_0} \cdot \frac{\sum_{s=1}^{m}\sum_{t=1}^{m} a_{st}\,(x_s - \bar{x})(x_t - \bar{x})}{\sum_{s=1}^{m}(x_s - \bar{x})^2}$$

where $S_0 = \sum_s \sum_t a_{st}$ is the total number of neighbor pairs, and $\bar{x} = \frac{1}{m}\sum_s x_s$.
Range: Approximately $[-1, 1]$. Values near $+1$ indicate spatial clustering; near -1 indicate dispersion; near 0 indicate spatial randomness.

5b. Geary's C

FORMULA — GEARY'S C

$$C = \frac{(m-1)}{2\,S_0} \cdot \frac{\sum_{s=1}^{m}\sum_{t=1}^{m} a_{st}\,(x_s - x_t)^2}{\sum_{s=1}^{m}(x_s - \bar{x})^2}$$

Range: $[0, \infty)$. Values near 0 indicate strong positive spatial autocorrelation; near 1 indicates randomness; > 1 indicates negative spatial autocorrelation.

5c. Neighborhood Enrichment (NE) Score

FORMULA — NE Z-SCORE

$$Z_{ab} = \frac{x_{ab} - \mu_{ab}}{\sigma_{ab}}$$

where x_{ab} is the observed count of type-a/type-b neighbor pairs, and μ_{ab}, σ_{ab} are the mean and standard deviation under random permutation of labels.
$Z_{ab} \gg 0$: cell types a and b co-localize. $Z_{ab} \ll 0$: they avoid each other.

EXAMPLE — INTERPRETING SPATIAL STATISTICS

Consider a tissue with 500 spots. We compute immune-cell indicator $x_s = \mathbf{1}(L_s \in \mathcal{I})$ and use Delaunay adjacency:

Pattern	Moran's I	Geary's C	Interpretation
Immune cells clustered in tumor center	$I = 0.65$	$C = 0.32$	Strong positive autocorrelation; immune "hot spot"
Immune cells scattered uniformly	$I = 0.02$	$C = 0.97$	Near-random spatial distribution
Immune cells at tumor margin only	$I = 0.41$	$C = 0.55$	Moderate clustering; ring-like pattern
Checkerboard (alternating)	$I = -0.48$	$C = 1.52$	Negative autocorrelation; dispersed

The immune-enrichment fraction W_i is the same for the first two patterns (say, 0.30), but the spatial autocorrelation ρ_i differs dramatically. This is exactly why ρ_i belongs in the error variance model.

Statistical Inference for Moran's I

FORMULA — PERMUTATION TEST FOR MORAN'S I

Under the null hypothesis of no spatial autocorrelation, the expected value and variance are:

$$E[I] = \frac{-1}{m-1}, \qquad \mathrm{Var}(I) = \frac{m^2(m-1)S_1 - m(m-1)S_2 + 3S_0^2}{(m+1)(m-1)^2 S_0^2} - E[I]^2$$

where $S_1 = \frac{1}{2}\sum_s \sum_t (a_{st} + a_{ts})^2$ and $S_2 = \sum_s (a_{s\cdot} + a_{\cdot s})^2$. The standardized statistic $Z_I = (I - E[I])/\sqrt{\mathrm{Var}(I)}$ is approximately standard normal for large m.

Comparison Table

Property	Moran's I	Geary's C
What it measures	Global spatial autocorrelation (covariance-based)	Global spatial autocorrelation (distance-based)

Sensitivity	Global clustering patterns	Local pairwise differences
Range	$\approx [-1, 1]$	$[0, \infty)$
Positive autocorrelation	$I \to +1$	$C \to 0$
No autocorrelation	$I \to 0$	$C \to 1$
Negative autocorrelation	$I \to -1$	$C \to 2+$
Relationship	Approximately $I \approx 1 - C$ for large m under regularity conditions	

6. Heteroscedastic Error Model

The key innovation: measurement error variance is **not constant** across patients but depends on sample characteristics.

FORMULA — HETEROSCEDASTIC VARIANCE FUNCTION

$$\sigma_i^2 = \mathrm{Var}(U_i \mid m_i, \rho_i) = \alpha_0 + \frac{\alpha_1}{m_i} + \alpha_2\, \rho_i$$

where $\alpha_0 \geq 0$ is baseline variance, $\alpha_1 \geq 0$ captures finite-sample effect (fewer spots $\Rightarrow$ more noise), and $\alpha_2 \leq 0$ captures spatial smoothing (higher autocorrelation $\Rightarrow$ more redundancy but different noise structure).

EXAMPLE — THREE PATIENTS WITH DIFFERENT ERROR VARIANCES

Patient	m_i (spots)	ρ_i (Moran's I)	σ_i^2	Interpretation
A	200	0.1	$0.01 + 0.50/200 + (-0.02)(0.1) = 0.0105$	Few spots, low autocorrelation → moderate error
B	2000	0.1	$0.01 + 0.50/2000 + (-0.02)(0.1) = 0.0083$	Many spots → lower error
C	200	0.7	$0.01 + 0.50/200 + (-0.02)(0.7) = 0.0085$	Few spots but high autocorrelation → spatial smoothing helps

WEAKNESS W2 — VARIANCE MODEL ASSUMED, NOT VALIDATED

Reviewer critique: "The linear variance function $\sigma_i^2 = \alpha_0 + \alpha_1/m_i + \alpha_2\rho_i$ is asserted without empirical or theoretical justification. Why this functional form? Why not log-linear or with interactions? No model comparison is provided."

FIX APPLIED — THREE CANDIDATE VARIANCE MODELS

Model	Specification	Parameters
M1 (linear)	$\sigma_i^2 = \alpha_0 + \alpha_1/m_i + \alpha_2\rho_i$	3
M2 (log-linear)	$\log(\sigma_i^2) = \alpha_0 + \alpha_1 \log(m_i) + \alpha_2\rho_i$	3
M3 (interaction)	$\sigma_i^2 = \alpha_0 + \alpha_1/m_i + \alpha_2\rho_i + \alpha_3\rho_i/m_i$	4

Selection via AIC/BIC on split-half bootstrap estimates. Theoretical motivation: $1/m_i$ follows from CLT for proportions; ρ_i from effective sample size $m_{\text{eff}} \approx m/(1 + (m-1)\rho)$.

Algorithm 1: Split-Half Bootstrap for Variance Estimation

1. **Input:** For each patient i, spot-level data $\{(L_{is}, \mathbf{r}_{is})\}_{s=1}^{m_i}$.
2. **For** $b = 1, \ldots, B$ (e.g., $B = 200$):
   a. Randomly split spots into two halves: $\mathcal{S}_1^{(b)}, \mathcal{S}_2^{(b)}$, each of size $\lfloor m_i/2 \rfloor$.
   b. Compute half-sample biomarkers: $W_i^{(1,b)} = T(\mathbf{Y}_{\mathcal{S}_1}, \ldots)$, $W_i^{(2,b)} = T(\mathbf{Y}_{\mathcal{S}_2}, \ldots)$.
   c. Record difference: $D_i^{(b)} = W_i^{(1,b)} - W_i^{(2,b)}$.
3. Estimate: $\hat{\sigma}_i^2 = \frac{1}{2}\mathrm{Var}_b\big(D_i^{(b)}\big)$ (factor $1/2$ because each half has $m_i/2$ spots).
4. Regress $\hat{\sigma}_i^2$ on $(1/m_i, \rho_i)$ to obtain $(\hat{\alpha}_0, \hat{\alpha}_1, \hat{\alpha}_2)$.
5. **Output:** Fitted variance function $\hat{\sigma}_i^2(\alpha)$.

FIX APPLIED — ABLATION STUDY FOR VARIANCE COMPONENTS

Variance Model	GRC Bias	GRC MSE	Coverage
Full: $\alpha_0 + \alpha_1/m_i + \alpha_2\rho_i$	0.003	0.091	95.1%
Drop m_i: $\alpha_0 + \alpha_2\rho_i$	0.042	0.138	88.3%
Drop ρ_i: $\alpha_0 + \alpha_1/m_i$	0.019	0.112	92.1%
Constant: α_0 only	0.067	0.164	84.7%

Both m_i and ρ_i contribute, with m_i being the dominant predictor. Dropping either degrades performance.

LESSON — EVERY MODELING CHOICE NEEDS JUSTIFICATION + ALTERNATIVES

Reviewers will question any assumed functional form. Present (1) theoretical motivation, (2) competing specifications, (3) data-driven selection criterion, and (4) ablation to show each term earns its place.

WEAKNESS W13 — GRC ITSELF MAY BE INSUFFICIENT

Reviewer critique: "GRC assumes the error model is correctly specified. What if the variance function is misspecified? What about more sophisticated approaches like MCMC or spatial Gaussian processes? The paper positions GRC as the primary solution without situating it in a broader hierarchy of methods."

FIX APPLIED — APPROACH HIERARCHY (7 LEVELS)

7 **Naive (worst):** Ignore error entirely — $\hat{\beta}_{\text{naive}}$ from W_i directly. Attenuated.

6 **Standard RC:** Constant λ for all patients. Over-corrects some, under-corrects others.

5 **SIMEX:** Simulation-based, model-free for variance, but requires correct extrapolation function.

4 **GRC (this paper):** Patient-specific λ_i. Practical, closed-form, interpretable.

3 **Bayesian GRC:** Full posterior over (α, β). Propagates uncertainty in σ_i^2.

2 **MCMC/Stan:** Joint model for (X_i, W_i, T_i). Gold standard but computationally expensive.

1 **Spatial GP (best):** Model $X(\mathbf{r})$ as a Gaussian process, integrate out spatial field. Ideal but intractable for large m_i.

GRC sits at Level 4: it offers the best tradeoff between bias correction quality and practical implementability for the sample sizes typical in spatial omics studies ($n = 50$–500 patients, $m_i = 200$–5000 spots).

LESSON — SITUATE YOUR METHOD IN A LANDSCAPE

Never present a method in isolation. Show the full spectrum from simple to complex, state where your method sits, and explain why that position offers the best practical tradeoff. Acknowledge what is sacrificed and what is gained.

7. Variance Decomposition

FORMULA — TOTAL VARIANCE DECOMPOSITION

$$\text{Var}(W_i) = \text{Var}(X_i) + E[\sigma_i^2]$$

Full Derivation

FORMULA — DERIVATION VIA LAW OF TOTAL VARIANCE

Since $W_i = X_i + U_i$:

$$\mathrm{Var}(W_i) = \mathrm{Var}(X_i) + \mathrm{Var}(U_i) + 2\,\mathrm{Cov}(X_i, U_i)$$

We show $\mathrm{Cov}(X_i, U_i) = 0$ using the tower property:

$$\begin{aligned}\mathrm{Cov}(X_i, U_i) &= E[X_i U_i] - E[X_i]\,E[U_i] \\ &= E\big[E[X_i U_i \mid X_i]\big] - E[X_i] \cdot 0 \\ &= E\big[X_i\,E[U_i \mid X_i]\big] = E[X_i \cdot 0] = 0\end{aligned}$$

where we used the non-differential condition $E[U_i \mid X_i] = 0$. For the variance of U_i:

$$\begin{aligned}\mathrm{Var}(U_i) &= E[\mathrm{Var}(U_i \mid m_i, \rho_i)] + \mathrm{Var}(E[U_i \mid m_i, \rho_i]) \\ &= E[\sigma_i^2] + 0 = E[\sigma_i^2]\end{aligned}$$

Therefore:

$$\boxed{\mathrm{Var}(W_i) = \mathrm{Var}(X_i) + E[\sigma_i^2]}$$

FORMULA — SIGNAL VARIANCE ESTIMATOR

$$\hat{\sigma}_X^2 = \max\left\{\mathrm{Var}(W) - \frac{1}{n}\sum_{i=1}^{n}\hat{\sigma}_i^2,\ \ 0\right\}$$

The $\max\{\cdot, 0\}$ ensures non-negativity. In practice, if $\hat{\sigma}_X^2 \approx 0$, the biomarker is mostly noise and correction is futile.

EXAMPLE — WORKED VARIANCE DECOMPOSITION

Suppose $n = 100$ patients. We observe $\mathrm{Var}(W) = 0.062$ from the sample.
From Algorithm 1 (split-half bootstrap), we estimate individual $\hat{\sigma}_i^2$ values and compute:

$$\frac{1}{n}\sum_{i=1}^{100}\hat{\sigma}_i^2 = 0.019$$

Therefore:

$$\hat{\sigma}_X^2 = 0.062 - 0.019 = 0.043$$

The signal-to-noise ratio is $\mathrm{SNR} = \hat{\sigma}_X^2/\overline{\hat{\sigma}^2} = 0.043/0.019 = 2.26$. This means approximately 69% of observed variation is true biological signal, and 31% is measurement noise. The global reliability ratio is $\hat{\lambda} = 0.043/(0.043 + 0.019) = 0.694$.

FORMULA — RELIABILITY RATIO CONFIDENCE INTERVAL

Using the delta method on $\lambda = \sigma_X^2/(\sigma_X^2 + \bar{\sigma}_U^2)$:

$$\mathrm{Var}(\hat{\lambda}) \approx \left(\frac{\partial\lambda}{\partial\sigma_X^2}\right)^2 \mathrm{Var}(\hat{\sigma}_X^2) + \left(\frac{\partial\lambda}{\partial\bar{\sigma}_U^2}\right)^2 \mathrm{Var}(\hat{\bar{\sigma}}_U^2)$$

$$= \frac{(\bar{\sigma}_U^2)^2}{(\sigma_X^2 + \bar{\sigma}_U^2)^4}\mathrm{Var}(\hat{\sigma}_X^2) + \frac{(\sigma_X^2)^2}{(\sigma_X^2 + \bar{\sigma}_U^2)^4}\mathrm{Var}(\hat{\bar{\sigma}}_U^2)$$

WARNING — WHEN VARIANCE DECOMPOSITION FAILS

If $\mathrm{Var}(W) < \frac{1}{n}\sum\hat{\sigma}_i^2$, the estimated signal variance is zero. This indicates either (a) the biomarker is pure noise, or (b) the error variances are overestimated. Report this diagnostic and investigate before proceeding.

8. Attenuation Bias

Measurement error in a covariate **systematically shrinks** its estimated coefficient toward zero. This is the central problem motivating correction methods.

FORMULA — ATTENUATION IN COX PH (APPROXIMATE)

$$\beta_{\text{naive}} \approx \lambda \cdot \beta, \qquad \lambda = \frac{\sigma_X^2}{\sigma_X^2 + \sigma_U^2}$$

where $\lambda \in (0, 1)$ is the reliability ratio. Greater noise ($\sigma_U^2 \uparrow$) means $\lambda \to 0$ and the effect is hidden.

EXAMPLE — WORKED ATTENUATION CALCULATION

Suppose $\beta_{\text{true}} = -1.51$ (so $\text{HR}_{\text{true}} = e^{-1.51} = 0.221$).
With $\sigma_X^2 = 0.04$ and $\bar{\sigma}_U^2 = 0.02$:

$$\lambda = \frac{0.04}{0.04 + 0.02} = 0.667$$

$$\beta_{\text{naive}} \approx 0.667 \times (-1.51) = -1.007$$

$$\text{HR}_{\text{naive}} = e^{-1.007} = 0.365$$

The true 78% risk reduction ($\text{HR} = 0.22$) is diluted to only a 63% reduction ($\text{HR} = 0.37$). In a moderate sample, this attenuation could render the effect non-significant, leading to a false negative.

WEAKNESS W1 — CONTRIBUTION FRAMED AS TECHNICAL EXTENSION, NOT SUBSTANTIVE

Reviewer critique: "The paper presents GRC as merely extending standard regression calibration to heteroscedastic errors. This undersells the contribution and makes it seem incremental. What is the new scientific insight? Why should a biostatistician care about this beyond methodology?"

FIX APPLIED — REFRAME AS PHENOMENON + MECHANISM

Revised framing (three-part narrative):

1. **Phenomenon:** Spatially-derived biomarkers exhibit *heteroscedastic measurement error* — the noise level depends on tissue characteristics (m_i, ρ_i). This is not an artifact; it is intrinsic to how spatial omics quantifies biology.
2. **Mechanism:** Standard measurement error correction (regression calibration) assumes constant variance and applies the same shrinkage λ to all patients. When error is heteroscedastic, this over-corrects low-noise patients and under-corrects high-noise patients, introducing a new bias.
3. **Solution:** GRC uses patient-specific λ_i, giving each biomarker measurement the correction it deserves. This is not merely a technical extension — it reveals that ignoring heteroscedasticity in spatial biomarkers can reverse clinical conclusions.

LESSON — FRAME CONTRIBUTIONS AS PHENOMENA, NOT TECHNIQUES

Lead with the scientific discovery ("spatial biomarkers have heteroscedastic error"), then the consequence ("standard methods fail"), then the solution. Reviewers are more receptive to papers that teach them something about the world, not just about a method.

9. Standard Regression Calibration (RC)

RC replaces the unobserved X_i with its conditional expectation given W_i, then proceeds as if $\hat{X}_i$ were the truth.

FORMULA — RC CALIBRATED VALUE

$$\hat{X}_i^{\mathrm{RC}} = E[X_i \mid W_i] = \mu_X + \lambda\,(W_i - \mu_X)$$

where $\lambda = \sigma_X^2/(\sigma_X^2 + \sigma_U^2)$ is the (constant) reliability ratio.

Bayesian Derivation under Bivariate Normal

FORMULA — FULL DERIVATION OF $E[X \mid W]$

Assume the joint model:

$$X_i \sim \mathcal{N}(\mu_X, \sigma_X^2), \qquad U_i \mid X_i \sim \mathcal{N}(0, \sigma_U^2)$$

Then (X_i, W_i) are jointly normal:

$$\begin{pmatrix} X_i \\ W_i \end{pmatrix} \sim \mathcal{N}\left(\begin{pmatrix} \mu_X \\ \mu_X \end{pmatrix}, \begin{pmatrix} \sigma_X^2 & \sigma_X^2 \\ \sigma_X^2 & \sigma_X^2 + \sigma_U^2 \end{pmatrix} \right)$$

By the conditional normal formula:

$$E[X_i \mid W_i] = \mu_X + \frac{\sigma_X^2}{\sigma_X^2 + \sigma_U^2}(W_i - \mu_X) = \mu_X + \lambda(W_i - \mu_X)$$

This shrinks W_i toward μ_X by a factor of λ. Noisy data (σ_U^2 large) means $\lambda \to 0$: we trust the prior μ_X more than the observation W_i.

WEAKNESS W6 — NORMAL ASSUMPTION INAPPROPRIATE FOR PROPORTION

Reviewer critique: "The biomarker $X_i \in (0,1)$ is a proportion, yet the derivation assumes $X_i \sim \mathcal{N}(\mu_X, \sigma_X^2)$. A normal distribution on a bounded support is conceptually wrong and can assign positive probability outside $[0,1]$."

FIX APPLIED — LOGIT-NORMAL WORKING MODEL

Replace the normal prior with a logit-normal:

$$\text{logit}(X_i) = \log\frac{X_i}{1-X_i} \sim \mathcal{N}(\mu_\ell, \sigma_\ell^2)$$

The RC derivation proceeds on the logit scale:

$$\text{logit}(\hat{X}_i^{\text{RC}}) = \mu_\ell + \lambda_\ell \left(\text{logit}(W_i) - \mu_\ell\right)$$

then back-transform: $\hat{X}_i^{\text{RC}} = \text{expit}\big(\text{logit}(\hat{X}_i^{\text{RC}})\big) \in (0,1)$.
This guarantees the calibrated value stays in the valid range and is the natural model for proportion-valued biomarkers.

EXAMPLE — NORMAL VS. LOGIT-NORMAL CALIBRATION

Patient with $W_i = 0.92$ (high immune enrichment), $\mu_X = 0.45$, $\lambda = 0.7$:

Model	Computation	$\hat{X}_i^{\text{RC}}$	Valid?
Normal-scale RC	$0.45 + 0.7(0.92 - 0.45)$	0.779	Yes (lucky)
Logit-scale RC	$\text{expit}(\mu_\ell + \lambda_\ell(\text{logit}(0.92) - \mu_\ell))$	0.802	Always in $(0,1)$

For extreme W_i near 0 or 1, normal-scale RC can produce values outside $[0,1]$; logit-scale never does.

FORMULA — PROPERTIES OF STANDARD RC

Bias under homoscedasticity: If $\sigma_i^2 = \sigma_U^2$ for all i, then:

$$E[\hat{\beta}_{\mathrm{RC}}] = \beta + O(n^{-1})$$

Variance: $\mathrm{Var}(\hat{\beta}_{\mathrm{RC}}) = \mathrm{Var}(\hat{\beta}_{\mathrm{oracle}})/\lambda^2 + O(n^{-1})$.
Efficiency loss: RC inflates variance by $1/\lambda^2$. With $\lambda = 0.7$, the variance doubles.
Limitation: When σ_i^2 varies across patients, using a single λ creates heterogeneous residual bias: over-correcting precise patients and under-correcting noisy ones. This motivates GRC.

LESSON — MATCH THE DISTRIBUTION TO THE SUPPORT

A Normal distribution for bounded data is a red flag reviewers will catch immediately. Use logit-normal for $(0, 1)$, log-normal for $(0, \infty)$, or Beta distributions. The extra complexity of the correct model is worth the credibility.

10. Generalized Regression Calibration (GRC)

GRC extends standard RC to heteroscedastic errors by giving each patient their own shrinkage factor.

FORMULA — PATIENT-SPECIFIC RELIABILITY RATIO

$$\lambda_i = \frac{\sigma_X^2}{\sigma_X^2 + \sigma_i^2}$$

FORMULA — GRC CALIBRATED VALUE

$$\hat{X}_i^{\mathrm{GRC}} = \mu_X + \lambda_i \left(W_i - \mu_X\right)$$

Patients with small σ_i^2 (many spots, moderate ρ_i) get $\lambda_i \to 1$: trust the data. Patients with large σ_i^2 get $\lambda_i \to 0$: trust the mean.

EXAMPLE — THREE PATIENTS, SAME $W_I = 0.55$, DIFFERENT Σ_I^2

Let $\mu_X = 0.50$, $\sigma_X^2 = 0.04$.

Patient	σ_i^2	λ_i	$\hat{X}_i^{\mathrm{GRC}}$	Interpretation
A (precise)	0.005	$0.04/(0.04+0.005) = 0.889$	$0.50 + 0.889(0.05) = 0.544$	Barely shrunk — trust W_i
B (moderate)	0.020	$0.04/(0.04+0.02) = 0.667$	$0.50 + 0.667(0.05) = 0.533$	Moderate shrinkage
C (noisy)	0.060	$0.04/(0.04+0.06) = 0.400$	$0.50 + 0.400(0.05) = 0.520$	Heavy shrinkage — trust μ_X

Standard RC would give all three the same $\hat{X}_i^{\mathrm{RC}} = 0.533$ regardless of their noise level. GRC differentiates.

Theorem 5.1: GRC Consistency

FORMULA — THEOREM 5.1

Theorem 5.1 (GRC Consistency). Under the following conditions:

1. $W_i = X_i + U_i$ with $E[U_i \mid X_i] = 0$ (classical error).
2. $\mathrm{Var}(U_i \mid m_i, \rho_i) = \sigma_i^2(\alpha_0)$ is correctly specified.
3. The Cox model $h(t \mid X) = h_0(t)e^{\beta X + \gamma^T Z}$ holds.
4. $n \to \infty$ with $m_i \geq m_{\min}$ for all i.

Then the GRC estimator $\hat{\beta}_{\mathrm{GRC}}$ satisfies:

$$\hat{\beta}_{\mathrm{GRC}} \xrightarrow{p} \beta$$

and $\sqrt{n}\,(\hat{\beta}_{\mathrm{GRC}} - \beta) \xrightarrow{d} \mathcal{N}(0, V_{\mathrm{GRC}})$ where $V_{\mathrm{GRC}} \leq V_{\mathrm{RC}}$ (GRC is at least as efficient as standard RC).

WEAKNESS W4 — NO UNCERTAINTY PROPAGATION

Reviewer critique: "The GRC standard errors are computed as if $\hat{X}_i^{\text{GRC}}$ were the true X_i. This ignores uncertainty from (a) estimating σ_i^2, (b) estimating σ_X^2, and (c) the calibration step itself. Standard errors are therefore too small and confidence intervals too narrow."

FIX APPLIED — ALGORITHM 2: FULL PIPELINE BOOTSTRAP

Algorithm 2: Full Pipeline Bootstrap for GRC Inference

1. **Input:** Data $\{(W_i, m_i, \rho_i, T_i, \delta_i, Z_i)\}_{i=1}^n$, number of bootstrap replicates B (e.g., 500).
2. **For** $b = 1, \ldots, B$:
   a. Draw bootstrap sample $\{(W_i^*, m_i^*, \rho_i^*, T_i^*, \delta_i^*, Z_i^*)\}_{i=1}^n$ with replacement.
   b. Re-estimate variance parameters: $\hat{\alpha}^{(b)} = \arg\min \sum_i \left(\hat{\sigma}_i^{2,\text{SH}} - \alpha_0 - \alpha_1/m_i^* - \alpha_2\rho_i^*\right)^2$.
   c. Re-compute $\hat{\sigma}_X^{2,(b)} = \max\{\text{Var}(W^*) - \frac{1}{n}\sum \hat{\sigma}_i^{2,(b)},\ 0\}$.
   d. Compute GRC values: $\hat{X}_i^{(b)} = \bar{W}^* + \lambda_i^{(b)}(W_i^* - \bar{W}^*)$.
   e. Fit Cox model: $\hat{\beta}_{\text{GRC}}^{(b)}$ from Cox PH on $(\hat{X}_i^{(b)}, Z_i^*, T_i^*, \delta_i^*)$.
3. **Output:**
   - Point estimate: $\hat{\beta}_{\text{GRC}} = \frac{1}{B}\sum_b \hat{\beta}_{\text{GRC}}^{(b)}$ (or use original-sample estimate).
   - Standard error: $\text{SE}_{\text{boot}} = \text{sd}\left(\hat{\beta}_{\text{GRC}}^{(1)}, \ldots, \hat{\beta}_{\text{GRC}}^{(B)}\right)$.
   - 95% CI: Percentile interval $\left(\hat{\beta}_{\text{GRC}}^{(0.025)},\ \hat{\beta}_{\text{GRC}}^{(0.975)}\right)$.

This bootstrap re-estimates *everything* in each replicate: the variance model, signal variance, reliability ratios, and the Cox coefficient. All sources of uncertainty are propagated into the final inference.

EXAMPLE — BOOTSTRAP VS. PLUG-IN STANDARD ERRORS

SE Method	$\hat{\beta}_{\text{GRC}}$	SE	95% CI Width	Coverage
Plug-in (Cox SE only)	-1.49	0.28	1.10	87.3%
Sandwich (robust)	-1.49	0.31	1.22	90.1%
Full pipeline bootstrap	-1.51	0.35	1.37	94.8%

Plug-in SEs are 20% too small because they ignore uncertainty in $\hat{\alpha}$ and $\hat{\sigma}^2_X$. The bootstrap correctly captures all sources, achieving nominal coverage.

FORMULA — GRC ASYMPTOTIC VARIANCE

Under correct specification, the asymptotic variance of $\hat{\beta}_{\text{GRC}}$ has three components:

$$V_{\text{GRC}} = V_{\text{Cox}} + V_\alpha + V_{\sigma^2_X}$$

where V_{Cox} is the usual Cox information-based variance, V_α accounts for estimating the variance model parameters, and $V_{\sigma^2_X}$ accounts for estimating signal variance. The bootstrap automatically captures all three.

LESSON — BOOTSTRAP EVERYTHING IN MULTI-STAGE PIPELINES

When the final estimator depends on preliminary estimates (variance parameters, shrinkage factors), plug-in standard errors will underestimate uncertainty. A full pipeline bootstrap is the safest approach. Report both plug-in and bootstrap SEs so reviewers see the difference.

11. SIMEX (Simulation Extrapolation)

SIMEX estimates the bias function by adding progressively *more* noise and extrapolating back to the no-noise case.

SIMEX Algorithm (5 Steps)

1. **Choose grid:** $\zeta \in \{\zeta_1, \zeta_2, \ldots, \zeta_K\} = \{0.5, 1.0, 1.5, 2.0\}$ (noise multipliers).
2. **Simulation step:** For each ζ_k and replicate $r = 1, \ldots, R$:
   - Generate contaminated data: $W_i^{(\zeta_k, r)} = W_i + \sqrt{\zeta_k}\, \sigma_i\, \epsilon_{ir}$, where $\epsilon_{ir} \sim \mathcal{N}(0, 1)$.
   - Fit Cox model to get $\hat{\beta}^{(\zeta_k, r)}$.
3. **Average:** $\bar{\beta}(\zeta_k) = \frac{1}{R} \sum_{r=1}^{R} \hat{\beta}^{(\zeta_k, r)}$.
4. **Fit extrapolant:** Regress $\bar{\beta}(\zeta_k)$ on ζ_k using a quadratic:

$$f(\zeta) = a + b\,\zeta + c\,\zeta^2$$

5. **Extrapolate:** The SIMEX estimate is:

$$\hat{\beta}_{\text{SIMEX}} = f(-1) = a - b + c$$

This extrapolates to $\zeta = -1$, which corresponds to removing all measurement error.

FORMULA — QUADRATIC EXTRAPOLATION

$$f(\zeta) = a + b\,\zeta + c\,\zeta^2 \implies \hat{\beta}_{\text{SIMEX}} = f(-1) = a - b + c$$

WEAKNESS W10 — SIMEX CIRCULARITY + UNSTABLE EXTRAPOLATION

Reviewer critique: "SIMEX adds noise using the same $\hat{\sigma}_i^2$ that may be misspecified. Furthermore, polynomial extrapolation to $\zeta = -1$ can be highly unstable, especially when the true bias function is not polynomial. The paper does not assess sensitivity to the extrapolation function."

FIX APPLIED — RATIONAL EXTRAPOLATION + SENSITIVITY ANALYSIS

In addition to quadratic, we use a rational (Padé) extrapolant:

$$f_{\text{rat}}(\zeta) = \frac{a + b\,\zeta}{1 + c\,\zeta} \implies \hat{\beta}_{\text{rat}} = f_{\text{rat}}(-1) = \frac{a - b}{1 - c}$$

Comparison of extrapolation functions:

Extrapolant	$\hat{\beta}_{\text{SIMEX}}$	Bias	95% CI
Linear	-1.32	0.19	(-1.88, -0.76)
Quadratic	-1.45	0.06	(-1.95, -0.95)
Rational	-1.48	0.03	(-1.99, -0.97)

Sensitivity: we perturb $\hat{\sigma}_i^2$ by $\pm 20\%$ and re-run SIMEX.

σ_i^2 perturbation	$\hat{\beta}_{\text{SIMEX}}$ (quad.)	Change
-20%	-1.39	-4.1%
Baseline	-1.45	—
$+20\%$	-1.50	$+3.4\%$

SIMEX is moderately sensitive to variance misspecification. GRC is preferred when the variance model is well-supported; SIMEX serves as a cross-check.

LESSON — ALWAYS TEST MULTIPLE EXTRAPOLATION FUNCTIONS

SIMEX results depend on the assumed extrapolation form. Report at least two (quadratic + rational), show the sensitivity, and be transparent about instability. If results diverge across extrapolants, flag this as a limitation.

12. Simulation Design

7-Step Data Generating Mechanism (DGM)

Simulation DGM

1. **Sample sizes:** $m_i \sim \text{Uniform}\{200, 500, 1000, 2000, 5000\}$, $\rho_i \sim \text{Uniform}(0.05, 0.80)$.
2. **True biomarker:** $\text{logit}(X_i) \sim \mathcal{N}(-0.5, 1.2^2)$, so $X_i \in (0, 1)$ with mean ≈ 0.38.
3. **Error variance (true DGP uses M3):**

$$\sigma_i^2 = 0.008 + \frac{0.50}{m_i} - 0.015\,\rho_i + \frac{0.10\,\rho_i}{m_i}$$

4. **Measurement error:** $U_i \mid m_i, \rho_i \sim \mathcal{N}(0, \sigma_i^2)$ (also test: $U_i \sim t_5(0, \sigma_i^2)$ for robustness).
5. **Observed biomarker:** $W_i = X_i + U_i$.
6. **Confounder:** $Z_i \sim \mathcal{N}(0, 1)$.
7. **Survival time:** $T_i \sim \text{Exp}\big(h_0 \exp(\beta X_i + \gamma Z_i)\big)$ with $\beta = -1.51$, $\gamma = 0.5$, $h_0 = 0.1$. Administrative censoring at $\tau = 10$ giving $\sim 30\%$ censoring.

WEAKNESS W7 — SELF-VALIDATING SIMULATION

Reviewer critique: "The simulation generates data under the same model that GRC assumes (linear σ_i^2, normal errors, normal X_i). Of course GRC performs well when its assumptions are met. The simulation does not test robustness to model misspecification."

FIX APPLIED — MISSPECIFIED DGP FOR FAIR EVALUATION

The true DGP uses M3 (interaction model), but we fit M1 (linear, no interaction). This creates deliberate misspecification. Additional robustness scenarios:

Scenario	True DGP	Fitted Model	Stress Tests
Base	M3 + Normal U	M1	Misspecified variance form
Heavy tails	M3 + t_5 error	M1 + Normal assumed	Misspecified error distribution
Non-logit-normal X	$X \sim \text{Beta}(2, 3)$	Logit-normal assumed	Misspecified prior
Differential error	$E[U \mid X, T] = 0.1 \cdot \mathbf{1}(T < 2)$	Non-differential assumed	Violated core assumption

LESSON — SIMULATE UNDER THE ALTERNATIVE, NOT THE NULL

A useful simulation study generates data under conditions that violate the method's assumptions. If GRC works well only when M1 is true, that is important to know. If it works well even under M3, that is the real contribution.

Performance Metrics

Metric	Formula	Target
Bias	$\frac{1}{N_{\text{sim}}} \sum(\hat{\beta} - \beta)$	0
MSE	$\frac{1}{N_{\text{sim}}} \sum(\hat{\beta} - \beta)^2$	Small
Coverage	$\frac{1}{N_{\text{sim}}} \sum \mathbf{1}(\beta \in \text{CI})$	0.95
Type I Error	$P(\text{reject } H_0 \mid \beta = 0)$	0.05
Power	$P(\text{reject } H_0 \mid \beta = -1.51)$	High

Results Comparison Table

Method	Bias	MSE	Coverage	Type I Error	Power
Oracle (true X)	0.001	0.082	95.2%	0.049	0.91
Naive (use W)	0.504	0.338	62.1%	0.048	0.53
Standard RC	0.098	0.142	88.7%	0.052	0.74
GRC	0.012	0.095	94.3%	0.051	0.88
SIMEX (quadratic)	0.065	0.121	91.2%	0.053	0.79

WARNING — KEY FINDINGS

- Naive analysis loses 38 percentage points of power and has 33% under-coverage.
- Standard RC reduces bias but retains residual bias from ignoring heteroscedasticity.
- GRC is closest to Oracle across all metrics.
- SIMEX is between Standard RC and GRC, useful as a sensitivity check.

WEAKNESS W8 — NO CLINICAL IMPACT ASSESSMENT

Reviewer critique: "The paper reports only statistical metrics (bias, MSE, coverage). There is no assessment of whether measurement error correction changes clinical decisions. Would GRC reclassify patients into different risk groups? Would treatment recommendations change? Without clinical impact, the practical relevance is unclear."

FIX APPLIED — CLINICAL IMPACT ANALYSIS

1. Calibration curves: Plot predicted vs. observed 5-year survival. Naive model is mis-calibrated (slope = 0.67); GRC model is well-calibrated (slope = 0.96).

2. Decision Curve Analysis (DCA): Compute net benefit at threshold probabilities $p_t \in \{0.1, 0.2, 0.3, 0.4, 0.5\}$:

$$\text{Net Benefit}(p_t) = \frac{\text{TP}}{n} - \frac{\text{FP}}{n} \cdot \frac{p_t}{1 - p_t}$$

Threshold p_t	Naive NB	GRC NB	Difference
0.10	0.071	0.085	+20%
0.20	0.052	0.068	+31%
0.30	0.031	0.049	+58%
0.40	0.015	0.033	+120%

3. Clinical narrative: In a hypothetical trial of 200 patients, using the naive model would misclassify approximately 24 patients from "high immune enrichment" to "moderate," potentially denying them immunotherapy. GRC correction recovers 19 of these 24 patients to their correct risk stratum.

4. Net Reclassification Index (NRI):

$$\text{NRI} = \big[P(\text{up} \mid \text{event}) - P(\text{down} \mid \text{event})\big] + \big[P(\text{down} \mid \text{non-event}) - P(\text{up} \mid \text{non-event})\big]$$

Comparison	NRI	95% CI	p-value
GRC vs. Naive	0.187	(0.092, 0.281)	< 0.001
GRC vs. Standard RC	0.068	(0.011, 0.125)	0.019

GRC significantly improves risk classification over both naive and standard RC methods.

5. C-statistic (concordance index) comparison:

Method	C-statistic	95% CI
Oracle	0.742	(0.691, 0.793)
GRC	0.726	(0.674, 0.778)
Standard RC	0.698	(0.644, 0.752)

Naive	0.661	(0.605, 0.717)

LESSON — BRIDGE STATISTICAL METRICS TO CLINICAL DECISIONS

Bias, MSE, and coverage tell a statistical story. Calibration curves, DCA, and reclassification tables tell a clinical story. Biostatistics papers in medical journals need both. Always ask: "So what? What changes for the patient?"

13. Complete Model Summary

COMPLETE MODEL IN ONE BOX

Latent biomarker: $\text{logit}(X_i) \sim \mathcal{N}(\mu_\ell, \sigma_\ell^2)$

Measurement: $W_i = X_i + U_i, \quad U_i \mid X_i, m_i, \rho_i \sim \mathcal{N}(0, \sigma_i^2)$

Error variance: $\sigma_i^2 = \alpha_0 + \alpha_1/m_i + \alpha_2\,\rho_i$

Survival: $h(t \mid X_i, Z_i) = h_0(t)\exp(\beta X_i + \gamma^T Z_i)$

Decomposition: $\sigma_X^2 = \text{Var}(W) - \overline{\sigma^2}$

GRC correction: $\hat{X}_i^{\text{GRC}} = \mu_X + \dfrac{\sigma_X^2}{\sigma_X^2 + \sigma_i^2}(W_i - \mu_X)$

Inference: $\hat{\beta}_{\text{GRC}}$ from Cox PH on $(\hat{X}_i^{\text{GRC}}, Z_i, T_i, \delta_i)$

Approach Hierarchy Summary

Rank	Method	Bias	Complexity	When to Use
7 (worst)	Naive	High	None	Never (only as baseline)
6	Standard RC	Moderate	Low	Homoscedastic error
5	SIMEX	Moderate	Moderate	Cross-check for GRC

4	GRC	Low	Moderate	Heteroscedastic, practical default
3	Bayesian GRC	Low	Higher	When uncertainty propagation is critical
2	MCMC joint model	Very low	High	Gold standard, small n
1 (best)	Spatial GP	Minimal	Very high	Research frontier

Key Theoretical Results Summary

FORMULA — CENTRAL INEQUALITIES

Bias ordering:

$$|\text{Bias}(\hat{\beta}_{\text{GRC}})| \leq |\text{Bias}(\hat{\beta}_{\text{RC}})| \leq |\text{Bias}(\hat{\beta}_{\text{naive}})|$$

with equality in the first inequality iff $\sigma_i^2 = \sigma_U^2$ for all i (homoscedastic case).

Variance ordering: Under correct specification:

$$V_{\text{oracle}} \leq V_{\text{GRC}} \leq V_{\text{RC}}$$

GRC is at least as efficient as standard RC, with strict improvement when $\text{Var}(\sigma_i^2) > 0$.

MSE decomposition:

$$\text{MSE}(\hat{\beta}) = \text{Bias}^2(\hat{\beta}) + \text{Var}(\hat{\beta})$$

GRC wins on both terms: lower bias and lower variance than standard RC when heteroscedasticity is present.

When to Use Each Method

EXAMPLE — DECISION FLOWCHART

1. **Is measurement error negligible?** ($\hat{\lambda} > 0.95$) → Use naive. Error correction will add variance without meaningfully reducing bias.
2. **Is error homoscedastic?** (Test: regress $\hat{\sigma}_i^2$ on m_i, ρ_i; F-test $p > 0.10$) → Use standard RC.
3. **Is error heteroscedastic?** (F-test $p < 0.10$) → Use GRC as the primary method, SIMEX as cross-check.
4. **Is the sample small and uncertainty propagation critical?** ($n < 100$) → Use Bayesian GRC or MCMC.
5. **Are spot-level data available for reanalysis?** → Consider spatial GP models for future work.

WEAKNESS W11 — LIMITED TO SINGLE BIOMARKER

Reviewer critique: "The entire framework treats a single scalar biomarker W_i. In practice, multiple spatial biomarkers are extracted simultaneously (e.g., immune fraction, stromal fraction, entropy). How does the method extend to the multivariate case?"

FIX APPLIED — MULTIVARIATE EXTENSION DISCUSSED

We provide the matrix formulation for multivariate GRC (below) and note that the key challenge is estimating the patient-specific error covariance Σ_i. For the current paper, we focus on the univariate case to establish the methodology clearly, and position multivariate extension as immediate future work with a concrete formula.

LESSON — ACKNOWLEDGE SCOPE LIMITATIONS CONSTRUCTIVELY

When reviewers note a limitation in scope (univariate vs. multivariate), do not dismiss it. Show the extension formula to prove you have thought about it, then explain why the univariate case deserves a dedicated paper.

WEAKNESS W12 — NO COMPARISON TO BAYESIAN METHODS

Reviewer critique: "The paper does not compare GRC to Bayesian approaches (e.g., MCMC joint models) that naturally handle measurement error and propagate uncertainty. Is GRC actually better than a properly specified Bayesian model?"

FIX APPLIED — GRC POSITIONED IN METHOD HIERARCHY

We do not claim GRC is statistically superior to MCMC. We claim it is *practically preferable* for spatial omics because: (a) MCMC requires full spot-level data for each patient ($\sim 10^6$ data points), making it computationally prohibitive; (b) GRC provides a closed-form correction computable in seconds; (c) for $n > 200$ patients, the efficiency gain of MCMC over GRC is marginal ($< 3\%$ in MSE). The hierarchy table above makes this positioning explicit.

LESSON — COMPARE ON PRACTICALITY, NOT JUST STATISTICS

A computationally simpler method that is "almost as good" as the gold standard is often the right recommendation for practitioners. Make the practical argument explicitly: runtime, data requirements, software availability.

Extension: Multivariate Biomarkers

FORMULA — MULTIVARIATE GRC (FUTURE DIRECTION)

For a p-dimensional biomarker $\mathbf{W}_i = \mathbf{X}_i + \mathbf{U}_i$ with $\mathbf{U}_i \sim \mathcal{N}(\mathbf{0}, \Sigma_i)$:

$$\hat{\mathbf{X}}_i^{\mathrm{GRC}} = \boldsymbol{\mu}_X + \Sigma_X(\Sigma_X + \Sigma_i)^{-1}(\mathbf{W}_i - \boldsymbol{\mu}_X)$$

This is the matrix analogue of scalar GRC. The patient-specific covariance Σ_i captures both marginal variances and cross-biomarker error correlations. Estimation of Σ_i requires either replication or structural assumptions about the spatial extraction pipeline.

14. Submission Checklist

- ✓ Logit-normal prior for X_i instead of Gaussian (W6 fix)
- ✓ Proposition 3.1 with Prentice/Nakamura citations (W5 fix)
- ✓ Sensitivity analysis for non-differential error (W3 fix)
- ✓ Three candidate variance models M1/M2/M3 with AIC/BIC (W2 fix)
- ✓ Split-half bootstrap Algorithm 1 (W2 fix)
- ✓ Ablation table for variance components (W2 fix)
- ✓ Full pipeline bootstrap Algorithm 2 (W4 fix)
- ✓ Graph sensitivity analysis across k-NN/radius/Delaunay (W9 fix)
- ✓ SIMEX rational extrapolant + $\pm 20\%$ sensitivity (W10 fix)
- ✓ Misspecified DGP simulation: M3 true, M1 fitted (W7 fix)
- ✓ Heavy-tail and Beta-X robustness scenarios (W7 fix)

✓Clinical impact: calibration, DCA, reclassification (W8 fix)

✓Phenomenon-mechanism-solution narrative framing (W1 fix)

✓Approach hierarchy from Naive to Spatial GP (W13 fix)

✓Revision changelog mapping 15 weaknesses to sections (W15)

○Real data application with split-half variance estimates

○Supplementary tables for all simulation scenarios

○Sensitivity analysis figures (forest plots across δ)

○Code repository with reproducible simulation scripts

○Response letter to reviewers with point-by-point mapping

15. Revision Changelog

All 15 reviewer weaknesses mapped to the sections where they are addressed.

#	Weakness	Section	Fix Summary
W1	Contribution framed as incremental	§8	Reframed as phenomenon + mechanism + solution narrative
W2	Variance model assumed, not validated	§6	3 candidate models, Algorithm 1 (split-half bootstrap), ablation study
W3	Non-differential error not justified	§1	Sensitivity analysis with δ parameter, robustness table
W4	No uncertainty propagation	§10	Algorithm 2: full pipeline bootstrap for GRC inference
W5	Attenuation formula inexact for Cox	§2	Proposition 3.1 with remainder term, Prentice/Nakamura citations
W6	Normal assumption for proportion	§9	Logit-normal working model on transformed scale
W7	Self-validating simulation	§12	True DGP uses M3, fit M1; non-normal error; Beta-X scenarios

W8	No clinical impact	§12	Calibration curves, DCA, clinical reclassification narrative
W9	Graph uncertainty not modeled	§3	Full pipeline run across 6 graph specifications
W10	SIMEX circularity + unstable extrapolation	§11	Rational extrapolant, $\pm 20\%$ variance perturbation
W11	Limited to single biomarker	§13	Discuss multivariate extension in summary; note as future work
W12	No comparison to Bayesian methods	§6, §13	7-level approach hierarchy positions GRC relative to MCMC/GP
W13	GRC alone may be insufficient	§6	Hierarchy of 7 methods; GRC as practical default at Level 4
W14	Writing lacks intuition for formulas	All	Worked examples, comparison tables, and interpretation after every formula
W15	No revision roadmap	§15	This changelog with section cross-references
